Redistributional Effects of the National Flood Insurance Program

Abstract This study examines the redistributional effects of the National Flood Insurance Program (NFIP) using a national database of premium, coverage, and claim payments at the county level between 1980 and 2006. Measuring progressivity as the departure from per capita county income proportionality we find that NFIP premiums are weakly regressive on an annual basis but become proportional as the time horizon is extended beyond a single year. In contrast, we find that NFIP claim payments are moderately progressive over all time horizons studied. In sum, we find no evidence that the NFIP disproportionately advantages richer counties.

Keywords: NFIP, progressivity, departure from proportionality

Redistributional Effects of the National Flood Insurance Program

1. Introduction

Damage from flood events is not covered by homeowners insurance policies and flood insurance is not widely available on the private market. Flood coverage is offered federally, however, through the National Flood Insurance Program (NFIP), established by the National Flood Insurance Act of 1968. Under current provisions, if communities choose to adopt minimum floodplain management policies, their residents become eligible for this insurance backed by the federal government. The goal of the NFIP is to contain the rising cost of damage caused by floods and to provide economically feasible relief to victims to help fuel recovery (Pasterick 1998). The NFIP is currently managed by the Federal Emergency Management Agency (FEMA) within the Department of Homeland Security. As of April, 2010, there were almost 5.6 million policies-in-force nationwide.

The NFIP has been the subject of renewed interest in recent years. Unprecedented losses associated with Hurricane Katrina and the other storms of the 2005 hurricane season sent the program deeply into debt, drawing the attention of people living in floodplains, insurance companies, and lawmakers. The NFIP was not designed to cover catastrophic loss years and its current debt to the U.S. Treasury from the 2005 claims—almost \$19 billion—has raised concerns about the program’s long-term financial solvency.¹ The NFIP will be unable to repay its debt given the current structure of premiums. Should Congress forgive it, taxpayers will bear the costs of returning the NFIP to solvency. In addition to debating debt forgiveness, lawmakers are also considering a wide range of other reforms to the program to address both financial

¹ Although NFIP is supposed to be funded with premiums collected from policyholders rather than with tax dollars, the program is, by design, not actuarially sound (see section 2 for more details). The program is not structured to build a capital surplus, is likely unable to purchase reinsurance to cover catastrophic losses, cannot reject high-risk applicants, and is subject to statutory limits on rate increases (GAO 2010).

soundness and concerns about who is and who should bear the burden of flood and hurricane costs.

Debate has emerged regarding the redistributive effects of the program. Little is known about who benefits from the NFIP and who bears the cost within the program. Some media accounts and advocacy groups have argued that the NFIP routinely subsidizes some of the wealthiest and most irresponsible property owners. They suggest that the program disproportionately benefits wealthy households and owners of vacation homes, many of which are expensive waterfront properties. Others have suggested that the program is a form of assistance for the poor who could not afford to purchase flood insurance at private market rates. Since these two arguments are countervailing, in this study we provide, as far as we are aware, the first empirical evidence to make an assessment of the overall redistributive effects of the NFIP.

Our analysis of the redistributive effects of the NFIP is based on a unique national database of the total dollars of premium, coverage, and claims paid per county per year in the U.S. from 1980 to 2006.² We measure progressivity as the departure of total county premiums and program payouts from per capita county income proportionality. We find that NFIP premiums are weakly regressive on an annual basis but become proportional as the time horizon is extended beyond a single year. In contrast, we find that NFIP claim payments are moderately progressive over all time horizons studied. In sum, we find no evidence that the NFIP disproportionately advantages richer counties.

The next section of the paper offers background on the NFIP relevant to understanding its redistributive effects. Section three discusses our data while the fourth section presents our

² Thanks to Tim Scoville for providing this data.

methods. The fifth section summarizes the results, and the sixth section concludes with a discussion of our findings and some important caveats to our conclusions.

2. Background on the NFIP

The NFIP was created in 1968 out of a concern that private companies were not willing or able to cover flood risk due to the catastrophic nature of losses, spatial correlation, and adverse selection. It was thought a government program could overcome these challenges. The NFIP was designed as a partnership between the federal government and local communities. FEMA maps the flood hazard in participating communities on Flood Insurance Rate Maps (FIRMs). Local governments can then adopt baseline regulations in high-hazard areas and, in exchange, the federal government provides insurance to homeowners and businesses. Homeowners can purchase up to \$250,000 of building coverage and up to \$100,000 of contents coverage. Business-owners can purchase up to \$500,000 each of both building and contents coverage.

Concerns about the costs of flooding and low take-up rates led Congress in 1973 to make the purchase of flood insurance mandatory for property-owners in 100-year floodplains with a mortgage from a federally backed lender. Take-up rates remained low in the early years of the program, but they have grown steadily over the decades. Still, following major flood events, concern is often expressed that many at-risk homeowners remain without coverage. An estimate of take-up rates in 100-year floodplains by RAND Corporation found high regional variation, with the south and west having the highest take-up rates of around 60%, while in the Midwest, take-up rates are only around 20-30% (Dixon et al. 2006). The NFIP is also highly concentrated geographically, with 40% of all policies-in-force nationwide located in Florida and close to 70%

of all policies located in just five states: Florida, Texas, Louisiana, California, and New Jersey (Michel-Kerjan and Kousky 2010).

There are two types of policies in the NFIP: actuarial policies and discounted policies. For both types of policies, rates for flood insurance vary by the flood zone indicated on the FIRM and structural characteristics of the property. Currently 78% of all policies-in-force are what FEMA calls “actuarial,” meaning they are priced using hydrologic models that include catastrophic loss year scenarios.³ The remaining 22% of policies are discounted. These are sometimes referred to as subsidized policies, but it is important to note that these are not subsidized by the general taxpayer. Rather, the discounted policies prevent the program from developing a catastrophe reserve. In 1981 it was decided that the combined revenue from the actuarial and the discounted policies should be enough to cover losses from the “average historical loss year.” After a series of rate increases on the discounted policies, this was achieved in 1986. Due to the discounted policies, therefore, the program does not build up a capital reserve to cover high loss years, such as 2005. If Congress forgives the debt incurred from the 2005 season, however, the general taxpayer will be subsidizing these policyholders.

The largest portion of the discounted policies is referred to as “pre-FIRM.” These structures were built before the FIRM for a community was available and were offered at discounted rates to encourage communities to join the program, to have homeowners cover at least some of the costs of flood losses (on the supposition that full rates would be so high that individuals would not insure and thus require more disaster aid), and to prevent the abandonment of otherwise economically viable structures through high premiums (Hayes and Neal 2009).

³ The GAO, however, recently reported that the data used is in some cases out-of-date or inaccurate and thus might be preventing the program from charging appropriate premiums (GAO 2008).

Post-FIRM, new construction is charged actuarial rates.⁴ Subsidized properties become required to pay actuarial rates when they are damaged at half the property value or when improvements increase their value by 50 percent or more (CBO 2007). It was, therefore, thought the subsidy would phase out quickly as structures were damaged or improved, but modern construction techniques have extended the life of buildings (Pasterick 1998, CBO 2007).

After Hurricane Katrina, the NFIP paid out more in claims than had previously been paid over the entire life of the program (Hayes and Neal 2009).⁵ The NFIP had to borrow heavily from the Treasury and its debt currently exceeds \$19 billion. While the NFIP had borrowed from the Treasury in previous years, it was always a small enough amount that it could subsequently be repaid. The program is unlikely, though, to be able to repay the current debt from Katrina. Forgiveness of the debt by Congress would create a subsidy from the general taxpayer to the program, particularly to those policyholders with discounted premiums.

3. Data

This study utilizes data on total claims paid, the number of policies-in-force, and the total premium intake at the U.S. county level from 1980 to 2006, which allows for a county-level analysis of how claims compare to premiums. Table 1 shows the descriptive statistics of the variables by states. Total premium intake during the period was about \$38 billion while the total claims payments were about \$37.4 billion.⁶ The top five states in terms of total paid claims – Louisiana, Florida, Texas, Mississippi, and Alabama – represent about 75% of the total claim

⁴ The subsidy applies only to the first \$35,000 of coverage on the building and \$10,000 on contents, although the mean and median claims in 2004 were below these limits (CBO 2007).

⁵ These are payments for insured properties. Congress also appropriated over \$60 billion in disaster relief for Hurricane Katrina. Some of this money does go into grants for individuals (who may be uninsured) but the amount is limited to just over \$30,000.

⁶ Premiums, coverage, and claim payments are adjusted to the 2006 level using a consumer price index for US city average.

payments for the nation as a whole. Louisiana has the highest claim payments which total \$16.5 billion or 44.2% of the total claim payments, followed by Florida (\$4 billion or 10.8% of the total payments) and Texas (\$3.5 billion or 9.4% of the total payments). This finding is largely driven by the unprecedented loss of the 2005 hurricane season on the Gulf Coast.⁷ When we exclude the year 2005, the ranking changes to Texas (17.8%), Florida (17.6%), Louisiana (13.0%), North Carolina (4.6%), and New Jersey (4.5%). The top five states in terms of the premium payment – Florida (34.6%), Texas (9.4%), Louisiana (9.1%), California (7.6%) and New Jersey (5.8%) – represent about 67% of the total amount. In 2006, more than 40% of the total NFIP policies-in-force were in Florida.

Table 2 shows the summary statistics by year. The number of NFIP policies has increased by about 170% between 1980 and 2006, an average increase of 6.5% per year. The premium intake has steadily increased over time, from rising prices and more policies-in-force, while the claim payment appears to be highly correlated with the occurrence of historical hurricanes.⁸ Hurricanes Charley and Ivan each made a landfall in Florida and Alabama in 2004, followed by Hurricanes Katrina and Rita along the Gulf Coast in 2005. The claim payments in 2004 and 2005 represent 6.3% and 48.2% of the total claims paid from 1980 to 2006, respectively. The average premium paid in 2006 was \$472. The average premium per policy between 1980 and 2006 is about \$432, and the average claim per policy during the period is approximately \$368.

⁷ The Congressional Budget Office estimated the value of capital stock destroyed by Hurricanes Katrina and Rita in the range of \$70 billion to \$130 billion, and the State of Louisiana estimated that the economic damage to the state alone could reach \$200 billion (US Government Accountability Office 2007).

⁸ Damage from hurricanes comes from storm surge, wind, and flooding. The NFIP does not cover wind damage, only flood losses from the storm surge and intense rainfall. During Katrina, flooding was also caused by levee failures.

Per capita personal income by year for each county is used in the analysis of the redistributive effect of the NFIP.⁹ Between 1980 and 2006, about 94% of U.S. counties had at least one NFIP policy-in-force and 80% of the counties filed at least one claim. Counties with at least one policy had on average per capita personal income of \$24,543 whereas counties without a policy had per capita personal income of \$24,923. Counties that filed claims had on average per capita personal income of \$24,846 and counties that did not file claims had, on average, per capita personal income of \$23,371. Per capita claim payment exhibited high variation—the standard deviation was about \$37.76, while the standard deviation of per capita premium was \$12.58. The highest per capita premium and per capita claim payment was \$251.62 and \$1,309.48, respectively.

4. The Measurement of NFIP Progressivity

In this study, we adapt the well-established tools of tax progressivity to evaluate the equity implications of the NFIP. Modern tax progressivity theory has at its roots Musgrave and Thin (1948), who were attempting to quantify an equitable approach to reducing taxes in the early post-war period. More recent developments in measurement of progressivity are well-summarized by Lambert (2002). In their most general form, tax progressivity measures are based on the familiar Lorenz curve measure of inequality and its associated concentration curve.

The most commonly used measure of progressivity focuses on the net redistributive effect of a fiscal action such as taxes, transfers, and other government programs. This net redistributive effect, which is often referred to as residual progression, measures the equalizing effect of the fiscal action. A fiscal action that improves upon the underlying income distribution is progressive, while a fiscal action that results in greater inequality is regressive. Alternatively,

⁹ Source: Regional Economic Information System, Bureau of Economic Analysis, U.S. Department of Commerce.

there are well-established measures of the departure from proportionality, also based on the Lorenz curve. This departure from proportionality, also known as liability progression, measures the share distribution of the policy effect across units with varying pre-policy income. Thus increases in progressivity are associated with enhanced departure from proportionality for pre-policy income distribution.

In the case of taxes, the crucial difference in these classes of measures is that the net redistributive effect is influenced by the magnitude of taxes relative to income (tax height), while departure from proportionality is scale invariant. When the level of tax height varies across time, these two measures can tell very different stories about changes in tax progressivity, but both are valid and offer some insight into changes in tax progressivity. Alternatively, when the tax height are the same the two measures provide identical progressivity rankings. In our case, NFIP premiums are small relative to total county income so we can ignore the “tax height” and focus on the departure from proportionality measure of progressivity.

We begin by defining the Lorenz curve and its related concentration curve. Let $0 \leq F^{-1}(p) \leq \infty$ be the inverse cumulative distribution function of x , and without loss of generality, let $\tau = F^{-1}(p)$. Following Bishop, Chow and Formby (1994), the Lorenz ordinates of x (for our analysis, x represents pre-NFIP county income) and the concentration ordinates of y (premiums or payments) can be written as follows:

$$(1) \quad L(\tau; x) = \mu_x^{-1} \int_0^\tau x f(x) dx = \mu_x^{-1} \int_0^\infty x I_\tau^x dF(x) = E[x I_\tau^x] / E[x],$$

where μ_x is the mean of x , $I_\tau^x = 1$ if $x \leq \tau$ and $I_\tau^x = 0$ otherwise,

$$(2) \quad C(\tau; y) = \mu_y^{-1} \int_0^\tau \int_0^\infty y f(x, y) dy dx = \mu_y^{-1} \int_0^\infty \int_0^\infty y I_\tau^x f(x, y) dy dx = E[y I_\tau^x] / E[y].$$

$L(\tau; x)$ represents the proportion of pre-NFIP per capita county income received by

counties with incomes x less than or equal to τ .¹⁰ $C(\tau; y)$ indicates the proportion of per capita payments received by counties with incomes x less than or equal to τ . A payout concentration curve, $C(\tau; z)$, orders payouts (z) by county per capita income. Unlike ordinary Lorenz curves a concentration curve can lie above the 45 degree line.

Following Kakwani (1976) and Jakobsson (1976), there is a progressive departure from proportionality of the flood insurance payouts if:

$$(3) \quad C(\tau; z) - L(\tau; x) \geq 0$$

with one strict inequality prevailing at some τ . We can evaluate NFIP per capita premiums in a similar manner; however, the sign on equation (3) must be reversed. For NFIP premiums to be progressive, counties must have paid premiums in a smaller proportion than their income.

The final issue to be considered in this section relates to which of the many indices of departure from proportionality (DP) to use to evaluate the flood insurance program. A frequent choice is the index based on the familiar Gini coefficient of inequality and its associated concentration index.

Given a continuous distribution $F(x)$, the covariance definition of the Gini index is

$$(4) \quad G_x = \frac{2}{\mu_x} \int_0^{\infty} xF(x)dF(x) - 1 = (2 / \mu_x) \text{cov}\{x, F(x)\}$$

and the associated concentration index for $y = g(x)$ is

$$(5) \quad C_y = \frac{2}{\mu_y} \int_0^{\infty} g(x)F(x)dF(x) - 1 = (2 / \mu_y) \text{cov}\{g(x), F(x)\}.$$

The departure from proportionality is measured as twice the area between the Lorenz curve for pre-program income and the concentration curve for payments or premiums:

¹⁰ It is important to note that in the construction of Lorenz curves and Gini coefficients we weight per capita income by population. Thus major urban counties are counted in proportion to their population size.

$$(6) \quad \Pi = C_T - G_X.$$

For payouts, a positive sign denotes payout progressivity, for premiums, the opposite is the case.¹¹ Finally, we note that these measures of progressivity are based on sample data. Inference tests for *DP* measures are provided by Bishop et al. (1994; 1998).

5. Results

We begin our analysis of NFIP progressivity by examining the departure from proportionality in detail for the year 2000. Table 3, Column 1 provides the Lorenz ordinates for per capita county income. Column 2 provides the concentration ordinates for per capita premiums and Column 3 provides the concentration ordinates for per capita NFIP payments. All three columns are population weighted.

Beginning with row one, we observe that the bottom 10 percent of counties received 6.2 percent of year 2000 income, paid 8.3 percent of the premiums and received 11.8 percent of NFIP payments. A progressive departure from proportionality requires that every premium decile be smaller (no larger) than its corresponding income decile. We find premiums in 2000, however, to be strictly regressive—for each decile a greater share of premiums is paid than the share of income received. This result is shown in Figure 1 where the concentration curve of per capita NFIP premiums lies everywhere above the Lorenz curve of per capita county income.

For NFIP payments, a progressive departure from proportionality requires that every premium decile be larger than its corresponding income decile. Comparing each payment decile value to its corresponding income value we find that NFIP payments are clearly progressive. These results are shown in Figure 2 where the concentration curve of NFIP per capita payments

¹¹ Recall that the Lorenz curve is a measure of equality and the Gini is a measure of inequality.

lies everywhere above the Lorenz curve of per capita county income. As noted above, the concentration curve can (and does in this case) lie above the 45 degree line.

The regressivity of NFIP premiums and the progressivity of NFIP payments can be summarized by examining the Gini and concentration coefficients given at the bottom of Table 3. Following Equation 6 we subtract the NFIP premium concentration index from the county income Gini coefficient to obtain the DP index, or $0.158 - 0.099 = 0.059$. For NFIP payments the concentration index is -0.129 . The negative value is obtained because the concentration curve of NFIP payments lies everywhere above the 45 degree line. The result is a DP index equal to $0.287 [0.158 - (-0.129)]$. From these DP indices we can conclude that NFIP premiums are mildly regressive (the DP index of 0.059 is close to zero) and the NFIP payments are moderately progressive.¹²

Table 4 provides the DP indexes for per capita NFIP premiums and payments on an annual basis for the period 1980 to 2006. We denote indexes that are not significantly different from zero at the five percent level using the pound sign (#). For NFIP premiums we find six such cases and for NFIP payments we find five such cases. A finding of no significant difference can be interpreted as premiums and payments in these years as being strictly proportional to income. Table 5 provides an ordinal evaluation of the departure from proportionality for 5 year time periods and for the overall period 1980-2006.

In 21 of the 27 individual years examined we find NFIP premiums to be regressive. We note that in most years the degree of regressivity is quite mild; the exception is 2005 which is quite regressive due to the immense losses in county income resulting from Hurricane Katrina. However, as we expand the time horizon to five year periods, the premiums become mostly

¹² A natural question to ask is why not to combine NFIP premiums and payments into an overall DP index. The answer is that this can result in negative values and the concentration index is not well defined over negative values.

proportional. Over the entire 1980 to 2006 time period (excluding 2005) we find that NFIP premiums are strictly proportional to county income.

In contrast to the proportionality of NFIP premiums, we find that NFIP payments are moderately progressive. There are two exceptions, where we find payouts to be regressive, Hurricane Andrew (South Florida, 1992) and Tropical Storm Allison (Houston, 2001). Hurricane Katrina stands out here as well—NFIP payments are massively progressive with a DP index of 0.9694, more than twice as large as the next largest DP index. This could be due to the fact that Hurricane Katrina caused substantial damage in low-income counties.

6. Discussion and Caveats

This study offers evidence on the progressivity of the NFIP using county level data from 1980 to 2006. From county level income data we calculate per capita income, per capita NFIP premiums, and per capita NFIP payments. All of our results are weighted by population size. Our findings indicate that the NFIP premiums are generally proportional over time periods greater than one year while generally mildly regressive on a year to year basis. In contrast, in most individual years and all five year time periods we find that NFIP payments are moderately progressive.

A number of caveats, however, are in order. First, our findings are by no means a complete measure of the redistributive effects of the NFIP as we have no information about the individual income of policyholders. We can thus only make statements about aggregate redistributive effects at the level of the county. Our findings would hold for individuals as well, if the income of those buying insurance was symmetric around the income of the county population. While ours is a useful first-order assessment, the largest redistributive effects in

the program are likely between those policyholders paying discounted rates and those paying actuarial rates. Unfortunately, the income of those subsidized homeowners is unavailable. More detailed analysis of the redistributive effects at the individual level is warranted since claims payments are concentrated on a few policies. Around 30% of claims payments are made to only about 1% of policyholders—these are the so-called repetitive loss properties. FEMA has estimated that around 90% of repetitive loss properties were constructed pre-FIRM (King 2005) and thus are also paying subsidized rates for their insurance.¹³

Second, we have examined the redistributive effect of the programs premiums and claims, not any infusion of taxpayer dollars.¹⁴ If Congress chooses to forgive the NFIP's debt, this will create a cross-subsidy from the general taxpayer to policyholders in the program that have been paying rates that did not include a catastrophe loading to cover an event like 2005. Understanding the redistributive effects of this debt forgiveness would require comparing the income of the general taxpayer to policyholders in the program.

Finally, it is worth emphasizing that assessing redistributive effects of a catastrophic risk over a short time period could be misleading. With low-probability risks like floods, there will be many years with no flood damage and then there could be a devastating year like 2005. Payments for these catastrophic events will have a dominating influence. For a flood event that has an annual probability of 1 in 100 or 1 in 500, a few decades is not enough data to accurately assess whether the prices are matching the risk. It just so happened that Katrina hit many low-income communities, leading to high payments in these areas. Should next year bring a devastating storm to West Palm Beach, Florida, the impact of claims payments might look much

¹³ Efforts have been made to bring these structures into compliance with floodplain regulations, to remove them completely, and to reduce the amount of the subsidy. Severe repetitive loss properties are being transferred to the NFIP Servicing Agent's Special Direct Facility (SDF). The properties are eligible for special mitigation grants.

¹⁴ See Wildasin (2008) for a discussion of federal commitments to insure losses from future disasters.

more regressive. In our own analysis we find the NFIP payments to be regressive in 1992 (Hurricane Andrew) and 2001 (Tropical Storm Allison).

If the risks of flooding can be accurately modeled, then an insurance program should not have any redistributive effect. Premiums paid should be proportional to the value of the insured structure and the risk that it faces. The NFIP, however, is a government program and its pricing and policies have been subjected to political pressure. This first-order analysis suggests that this influence has not been directed disproportionately at helping higher income communities, as some critics of the NFIP claim.

Note: All states and the District of Columbia are included in the data. The asterisks denote the average values from 1980 to 2006. Dollars are measured in 2006 USD.

**Table 3. Lorenz and Concentration Ordinates for County Income,
NFIP Premiums, and NFIP Payouts, 2000¹**

Lorenz		Concentration Ordinates	
Decile	Income (1)	Premiums (2)	Payments (3)
1	0.062	0.083	0.118
2	0.135	0.165	0.294
3	0.213	0.260	0.394
4	.0300	0.301	0.528
5	0.389	0.393	0.581
6	0.488	0.542	0.645
7	0.589	0.613	0.772
8	0.698	0.687	0.852
9	0.830	0.854	0.913
1.0	1.000	1.000	1.000
Gini²	0.158	0.099	-0.129
DP Index	--	0.059	0.287

¹Country income, NFIP premiums and payouts are in per capita terms, weighted by population.

²Strictly speaking, column 1 provides a Gini coefficient and columns 2 and 3 provide corresponding concentration indexes.

Table 4
Departure From Proportionality Indexes,
NFIP Premiums and Payouts, 1980-2000

Year	Premiums¹	Payout²
1980	0.0225 #	0.2323
1981	-0.0295 #	0.0398 #
1982	-0.0159 #	0.1018
1983	0.0446	0.1450
1984	0.0368	0.2873
1985	0.0372	0.2846
1986	0.0540	0.0950 #
1987	0.0687	0.2626
1988	0.0446	0.1416
1989	0.0962	0.5188
1990	0.0368 #	0.3432
1991	0.0548	0.0752 #
1992	-0.0003 #	-0.2460
1993	0.0321	0.4629
1994	0.0291	0.2170
1995	0.0615	0.3112
1996	0.0392	0.2824
1997	0.0499	0.3776
1998	0.0519	0.2761
1999	0.0761	0.1541 #
2000	0.0594	0.2872
2001	0.0571	-0.2848
2002	0.0730	0.3211
2003	0.0519	0.1094 #
2004	0.0259 #	0.4102
2005	0.1332	0.9694
2006	0.0245	0.1126

¹Positive number indicates regression, lower income countries contribute more than their income share.

²Positive number indicates progressive, lower income countries received more than their income share.

Note: The pound sign (#) denotes insignificance at the five percent level, implying strict proportionality.

Table 5
Departures from Proportionality, NFIP Premium and Payouts,
Alternative Time Periods

Periods	Premiums	Payouts
1980-1985	Proportional	Progressive
1986-1990	Proportional	Progressive
1991-1995	Proportional	Progressive
1996-2000	Regressive	Progressive
2001-2006*	Proportional	Progressive
1980-2006*	Proportional	Progressive

*Note: The year 2005 was excluded in the 2001-2006 and 1980-2006 periods.
